Generative Models Discriminative vs Generative

Understanding Machine Learning

Archetype: Naïve Bayes

probabilistic model:

$$P(Y|X_1, \cdots, X_p) = \frac{P(Y, X_1, \cdots, X_p)}{P(X_1, \cdots, X_p)} = \frac{P(Y)P(X_1, \cdots, X_p|Y)}{P(X_1, \cdots, X_p)} \propto P(Y)P(X_1, \cdots, X_p|Y)$$
Bayes' rule constant to be estimated

approach:

- 1. estimate $P(Y, X) \rightarrow$ generative model (can be used to generate new samples)
- 2. calculate P(Y|X) from $P(Y,X) \rightarrow$ used for discriminative task (classification)

Independence Assumption

(naïve) assumption: conditional independence of features given target

$$P(X_j|Y,X_1,\cdots,X_{j-1},X_{j+1},\cdots,X_p) = P(X_j|Y)$$

$$\Rightarrow P(Y|X_1,\dots,X_p) = \frac{P(Y)\prod_{j=1}^p P(X_j|Y)}{P(X_1,\dots,X_p)}$$

- > independent feature contributions (ignoring feature correlations)
- > robust against curse of dimensionality

Estimation of Feature Contributions

separate estimations of $P(X_j|Y)$ for each feature

requires assumption of distributions (e.g., Gaussian naïve Bayes) or non-parametric methods (kernel density estimation)

Gaussian feature likelihoods:

$$P(x_{ij}|y) = \frac{1}{\sqrt{2\pi\sigma_{y,j}^2}} \exp\left(-\frac{(x_{ij}-\mu_{y,j})^2}{2\sigma_{y,j}^2}\right)$$

parameter estimation (e.g., mean and variance of Gaussians) can be done with maximum likelihood method (y known in training)

→ no Bayesian methods needed

Maximum a Posteriori Classification

$$\hat{y}_i = \underset{y}{\operatorname{argmax}} P(y) \prod_{j=1}^p P(x_{ij}|y)$$

despite potentially inaccurate probability estimates (due to naïve independence assumption), good identification of correct class via maximum probability

→ bad for regression tasks (if independence assumption is too naïve, i.e., features are correlated)

Generative vs Discriminative Models

generative models: predict joint probability P(Y, X) (what allows to create new data samples) or directly generate new data samples

or just $P(X) \rightarrow$ unsupervised (or self-supervised) learning

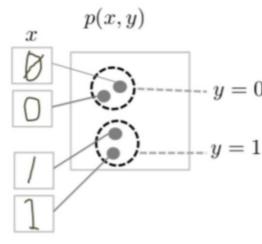

discriminative models: predict conditional probability (or probability distribution for regression) P(Y|X) or directly output (label for classification, real value for regression)

task of generative models more difficult: model full data distribution rather than merely find patterns in inputs to distinguish outputs

discriminative model

generative model

source

Naïve Bayes and Logistic Regression

generative-discriminative pair of classification algorithms

- binary case: logit of naïve Bayes' outputs, $\log\left(\frac{P(y_i=1|x_i)}{P(y_i=0|x_i)}\right)$, corresponds to output of logistic regression's linear predictor
- for discrete inputs or Gaussian naïve Bayes: naïve Bayes can be reparametrized as linear classifier

for discriminative task: identical in asymptotic limit (infinite training samples) if independence assumption holds (otherwise naïve Bayes less accurate)

naïve Bayes has greater bias but lower variance than logistic regression \rightarrow to be preferred for scarce training data (if bias, i.e., independence assumption, correct)

Data Generation

generative models can be used for discriminative tasks (although potentially inferior to direct discriminative methods)

but generative methods do more than discriminative ones: model full data distribution

→ allows generation of new data samples (can be images, text, video, audio, code like SQL or Python, proteins, materials, time series, structured data, ...)

large (auto-regressive) language models examples of generative models

Deep Learning for Generative Al

Depending on the application, there are currently two dominant approaches for generative AI:

• text generation: decoder LLMs

 image synthesis: diffusion models (usually conditioned on text by transformers)

note the difference between image synthesis and multimodal understanding in LLMs (images as additional input sequences to transformer, tokenized by splitting into patches)

Image Synthesis

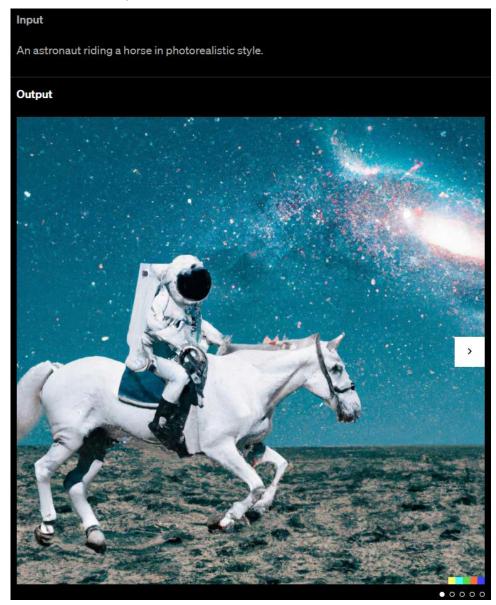

idea: generate new images as variations of training data

condition generation on text prompts: text-to-image

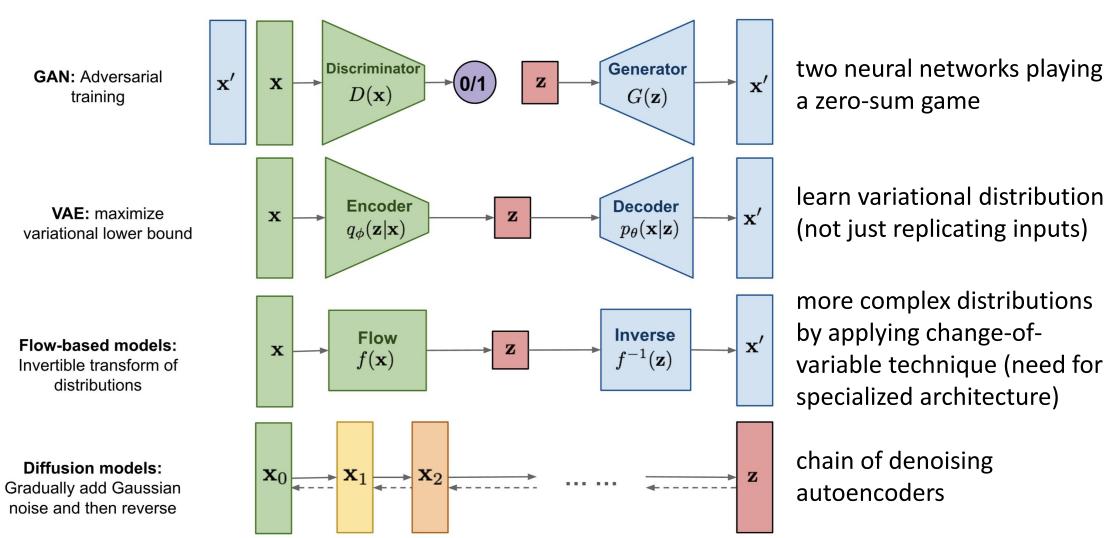

trade-off between diversity and fidelity

SOTA: (guided) diffusion models compared to text generation, additional mechanism needed (e.g., diffusion) to create more complex structures

example: DALL-E 2

Different Model Types for Image Synthesis

source

→ generalization: <u>flow matching</u>

Generative Adversarial Networks (GAN)

Indirect Training via Discriminator

two neural networks playing a zero-sum game:

- the generator network G generating new (fake) samples
- the discriminator network D trying to distinguish between real and fake samples

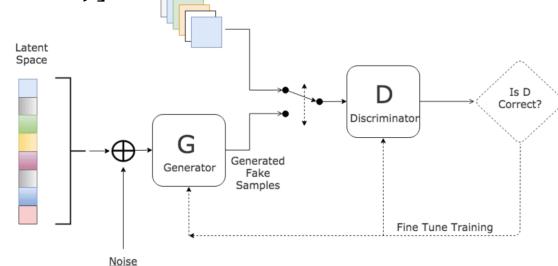

idea: G not trained directly to minimize reconstruction error of real samples, but to fool D \rightarrow self-supervised approach

Formulation

common loss for generator and discriminator:

$$L(\boldsymbol{x}_i) = E_{\boldsymbol{x} \sim p_r(\boldsymbol{x})}[\ln D(\boldsymbol{x}_i)] + E_{\boldsymbol{x} \sim p_g(\boldsymbol{x})}[\ln (1 - D(\boldsymbol{x}_i))]$$

- G trying to minimize
- D trying to maximize

generator: decomposition into latent space (parameters of generator network) and noise (sampled from, e.g., Gaussian distribution)

source

Properties

implicit generative model: do not estimate likelihood function

for optimal D, GAN loss quantifies similarity between generative data distribution $p_{\it g}$ and real data distribution $p_{\it r}$ by Jensen-Shannon divergence

$$D_{JS}(p||q) = \frac{1}{2} D_{KL}\left(p||\frac{p+q}{2}\right) + \frac{1}{2} D_{KL}\left(q||\frac{p+q}{2}\right)$$

for optimal values of both G and D: $p_g = p_r$ and D = 0.5

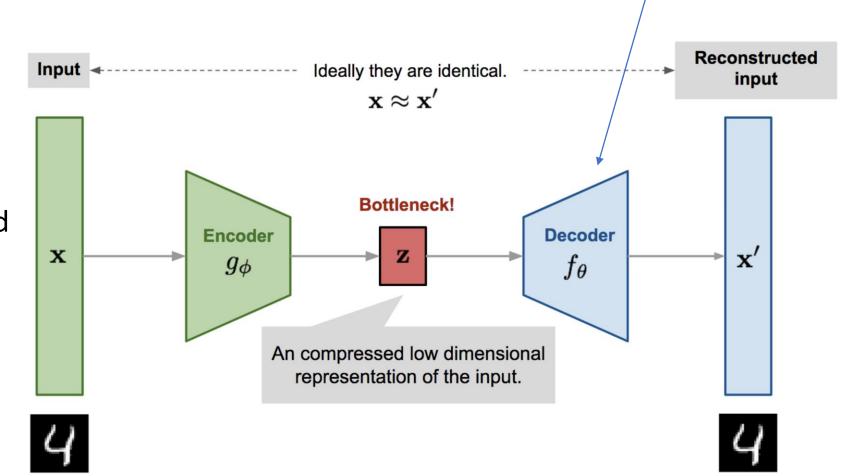

issue: potentially unstable training

Variational Autoencoders (VAE)

Recap: Autoencoder

(deep) encoder network
(deep) decoder network
learned together by
minimizing differences
between original input and
reconstructed input
(expressed as losses)

compressed intermediate representation: dimensionality reduction

source

up-sampling, for example,

by transposed convolutions

Autoencoder Architecture for Generative Tasks

goal: generation of variations of input data rather than compressed representation

→ learn variational distribution instead of identity function

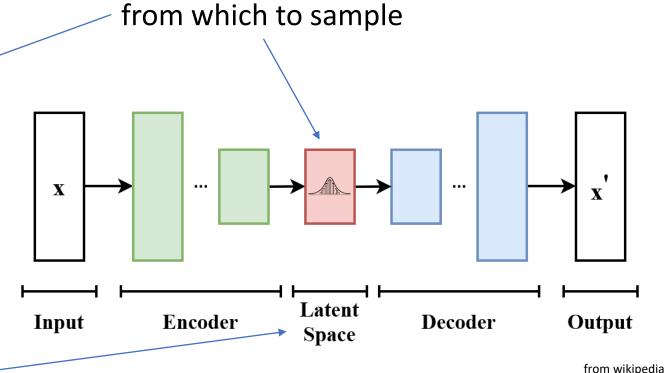

to be precise: parametrized variational distribution of latent encoding variables z

prior (simple distribution, in usual VAE:

Gaussian): $p_{\theta}(\mathbf{z})$

posterior:
$$p_{\theta}(\mathbf{z}|\mathbf{x}) = \frac{p_{\theta}(\mathbf{x}|\mathbf{z})p_{\theta}(\mathbf{z})}{\int p_{\theta}(\mathbf{x}|\mathbf{z})p_{\theta}(\mathbf{z})d\mathbf{z}}$$

 $p_{\theta}(x)$: mixture of Gaussians

Variational Bayesian Method

Encoder and Decoder Networks

encoder: find posterior $p_{\theta}(\mathbf{z}|\mathbf{x})$ unfortunately, generally intractable

 \rightarrow approximate by $q_{\phi}(\mathbf{z}|\mathbf{x})$

VAE: $q_{\phi}(\mathbf{z}|\mathbf{x})$ expressed by neural network with weights ϕ

 \Rightarrow amortized inference: $q_{\phi}(z|x)$ learned in training, z inferred from x in prediction (sharing variational parameters across all data points)

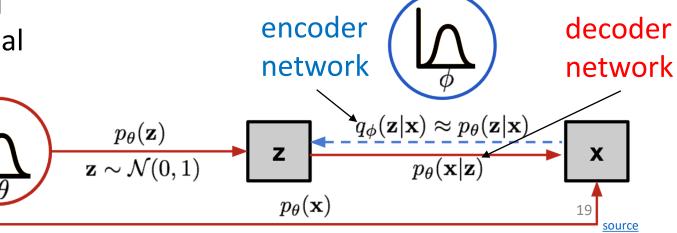

in VAE: network weights $oldsymbol{ heta}$

decoder: generate new sample x_i

- 1. sample z_i (from Gaussian)
- 2. generate x_i (similar to real data)

 \rightarrow maximize: $p_{\theta}(x_i) = \int p_{\theta}(x_i|\mathbf{z}) p_{\theta}(\mathbf{z}) d\mathbf{z}$

(integral over z expensive \rightarrow use only likely codes z given input x: need for encoder)

VAE Loss: ELBO

VAE loss function to be minimized according to network weights:

$$L(\mathbf{x}_i; \boldsymbol{\theta}, \boldsymbol{\phi}) = -\ln p_{\boldsymbol{\theta}}(\mathbf{x}_i) + D_{KL} \left(q_{\boldsymbol{\phi}}(\mathbf{z}|\mathbf{x}_i) || p_{\boldsymbol{\theta}}(\mathbf{z}|\mathbf{x}_i) \right)$$

maximize likelihood of observed data (minimize reconstruction error)

and

minimize difference of approximation $q_{\phi}(\mathbf{z}|\mathbf{x}_i)$ to exact posterior $p_{\theta}(\mathbf{z}|\mathbf{x}_i)$

20

can be interpreted as regularizer

corresponds to maximizing evidence lower bound (ELBO), i.e., maximizing lower bound of probability to generate real data sample:

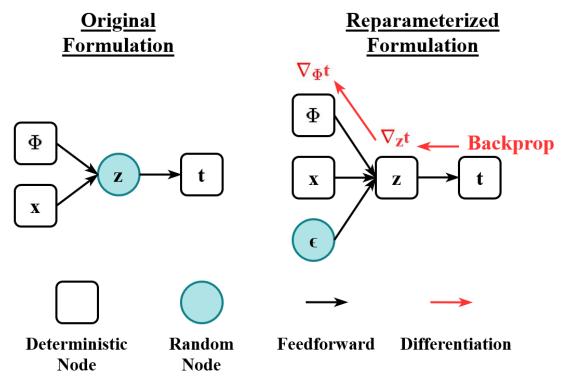

$$\ln p_{\boldsymbol{\theta}}(\boldsymbol{x}_i) \ge \ln p_{\boldsymbol{\theta}}(\boldsymbol{x}_i) - D_{KL}\left(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}_i)||p_{\boldsymbol{\theta}}(\boldsymbol{z}|\boldsymbol{x}_i)\right) = E_{\boldsymbol{z} \sim q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}_i)}\left[\ln \frac{p_{\boldsymbol{\theta}}(\boldsymbol{x}_i, \boldsymbol{z})}{q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}_i)}\right]$$
non-negative

Reparameterization Trick

ightarrow gradient descent according to $oldsymbol{ heta}$ and $oldsymbol{\phi}$

issue: not readily possible for ϕ (expecatation over z, which is sampled from q_{ϕ})

 \rightarrow reparametrization to the rescue: express randomness in z by independent auxiliary variable ε

from wikipedia

Gaussian Approximation

Posterior and approximation

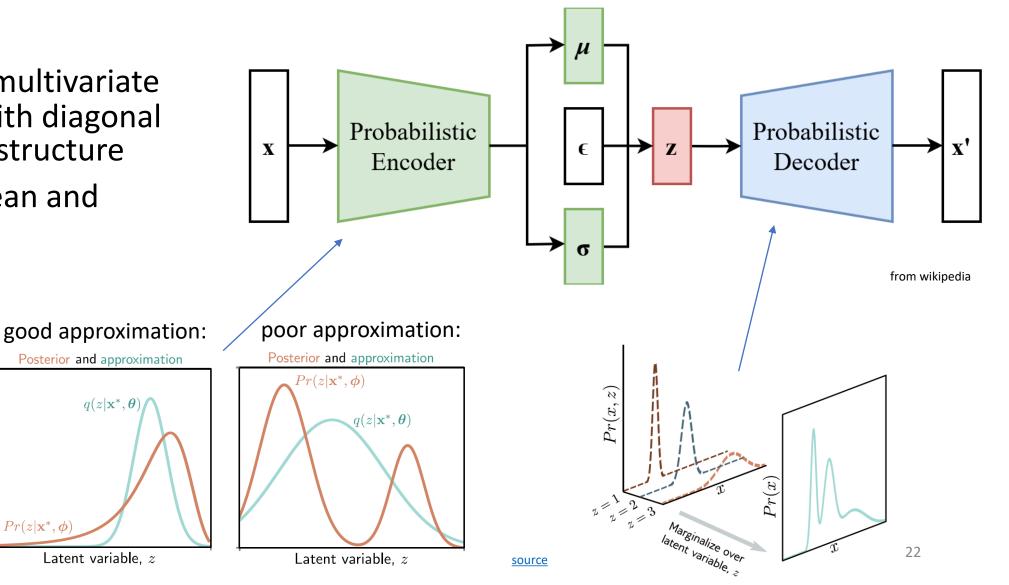

Latent variable, z

 $Pr(z|\mathbf{x}^*, \boldsymbol{\phi})$

 $q(z|\mathbf{x}^*, \boldsymbol{\theta})$

e.g., q_{ϕ} as multivariate Gaussian with diagonal covariance structure

→ learn mean and variance

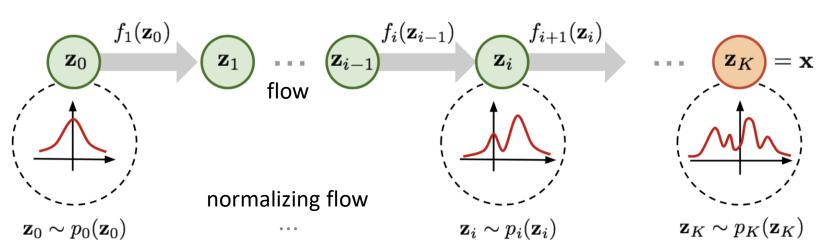

Flow-Based Methods

Normalizing Flows

idea: mapping of a simple probability distribution (often, standard normal distribution) into a complex one by sequence of invertible transformations (repeatedly applying the change-of-variable technique)

$$f(\mathbf{z}') = f(\mathbf{z}) \left| \det \frac{\delta f^{-1}}{\delta \mathbf{z}'} \right| = f(\mathbf{z}) \left| \det \frac{\delta f}{\delta \mathbf{z}} \right|^{-1}$$
$$\ln p_K(\mathbf{z}_K) = \ln p_0(\mathbf{z}_0) - \sum_{k=1}^K \ln \left| \det \frac{\delta f_k}{\delta \mathbf{z}_{k-1}} \right|$$

log-likelihood:

Usage in Generative Models

training: estimate maximum likelihood of normalizing flow (log-likelihood of last slide) by gradient descent (learn parameters θ of transformations f_{θ}^{-1} , e.g., to let $p_0(\mathbf{z})$ be Gaussian)

inference: sample from simple distribution $p_0(\mathbf{z})$ and transform it back to data distribution $p_K(\mathbf{x})$ via f_θ

advantages:

- instead of simple distributions like Gaussians, allow more complex latent encodings: real-world distributions usually much more complicated
- exact likelihood estimation (VAEs and diffusion models only return lower bound): allows density estimation (e.g., for anomaly detection)

Invertible Neural Networks

neural networks representing invertible/bijective functions can be used for normalizing flow transformations

- forward transformation to generate samples
- backward transformation to evaluate likelihoods

need for specialized architectures to construct reversible transform (e.g., affine coupling layers)

Diffusion Models

Idea

training: distort training data by successively adding random noise, then learn to reverse this process (denoising)

generation: sample random noise and run through the learned denoising process

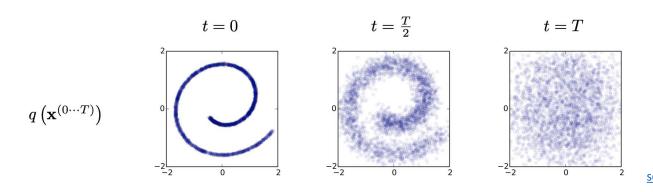

advantages: easy to train, produce high-quality/realistic samples can be interpreted as special case of hierarchical VAE (one latent variable generates another) with fixed encoder and latent space of same size as the data \rightarrow more sophisticated latent space than just Gaussian mixture in VAE

Forward Process

Markov chain of diffusion steps to slowly add Gaussian noise to data (inspired by non-equilibrium thermodynamics):

$$q(\mathbf{x}_{1:T}|\mathbf{x}_0) = \prod_{t=1}^{I} q(\mathbf{x}_t|\mathbf{x}_{t-1}), \quad q(\mathbf{x}_t|\mathbf{x}_{t-1}) = \mathcal{N}(\mathbf{x}_t; \sqrt{1-\beta_t}\mathbf{x}_{t-1}, \beta_t \mathbf{I})$$

- with variance schedule $\beta_1, ..., \beta_T$ (hyperparameters, increasing with t)
- large T and small $\beta_t \rightarrow$ same functional form for forward and reverse processes, ending up with isotropic Gaussian distribution for x_T

Reparametrization

conditional Gaussian distributions at each t:

sample
$$\epsilon \sim \mathcal{N}(0, \mathbf{I})$$
 and set $\mathbf{x}_t = \sqrt{1 - \beta_t} \mathbf{x}_{t-1} + \sqrt{\beta_t} \epsilon$

nice property: possible to directly sample x_t conditioned on x_0 (no need to apply q repeatedly)

$$\begin{aligned} \boldsymbol{x}_t &= \sqrt{\bar{\alpha}_t} \boldsymbol{x}_0 + \sqrt{1 - \bar{\alpha}_t} \boldsymbol{\epsilon} \\ q(\boldsymbol{x}_t | \boldsymbol{x}_0) &= \mathcal{N} \big(\boldsymbol{x}_t; \, \sqrt{\bar{\alpha}_t} \boldsymbol{x}_0, (1 - \bar{\alpha}_t) \mathbf{I} \big) \end{aligned}$$
 with $\alpha_t = 1 - \beta_t$, $\bar{\alpha}_t = \prod_{s=1}^t \alpha_s$

conditioning on x_0 also allows to handle $q(x_{t-1}|x_t,x_0)$

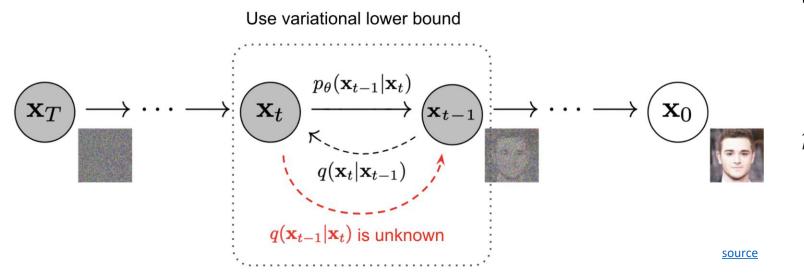

Reverse Process

to generate new data samples, one needs to learn to reverse the diffusion process (starting from pure noise): neural network learning to gradually denoise data

overall loss as sum of losses for each time step t

for each t: D_{KL} between two Gaussians (closed form) $q(x_{t-1}|x_t,x_0)$ and $p_{\theta}(x_{t-1}|x_t)$

→ corresponds to VAE loss: maximizing ELBO

time-dependent Gaussian parameters:

$$p(\mathbf{x}_T) = \mathcal{N}(\mathbf{x}_T; 0, \mathbf{I})$$

$$p_{\theta}(\mathbf{x}_{0:T}) = p(\mathbf{x}_T) \prod_{t=1}^{T} p_{\theta}(\mathbf{x}_{t-1} | \mathbf{x}_t)$$

$$p_{\theta}(\mathbf{x}_{t-1} | \mathbf{x}_t) = \mathcal{N}(\mathbf{x}_{t-1}; \boldsymbol{\mu}_{\theta}(\mathbf{x}_t, t), \boldsymbol{\Sigma}_{\theta}(\mathbf{x}_t, t))$$

Noise Prediction

reparametrization allows to learn added noise instead of Gaussian parameters:

Algorithm 1 Training	Algorithm 2 Sampling
1: repeat 2: $\mathbf{x}_0 \sim q(\mathbf{x}_0)$ 3: $t \sim \mathrm{Uniform}(\{1,\ldots,T\})$ 4: $\boldsymbol{\epsilon} \sim \mathcal{N}(0,\mathbf{I})$ 5: Take gradient descent step on $\nabla_{\theta} \left\ \boldsymbol{\epsilon} - \boldsymbol{\epsilon}_{\theta} (\sqrt{\bar{\alpha}_t} \mathbf{x}_0 + \sqrt{1 - \bar{\alpha}_t} \boldsymbol{\epsilon}, t) \right\ ^2$ 6: until converged	1: $\mathbf{x}_{T} \sim \mathcal{N}(0, \mathbf{I})$ 2: for $t = T, \dots, 1$ do 3: $\mathbf{z} \sim \mathcal{N}(0, \mathbf{I})$ if $t > 1$, else $\mathbf{z} = 0$ 4: $\mathbf{x}_{t-1} = \frac{1}{\sqrt{\alpha_{t}}} \left(\mathbf{x}_{t} - \frac{1-\alpha_{t}}{\sqrt{1-\bar{\alpha}_{t}}} \boldsymbol{\epsilon}_{\theta}(\mathbf{x}_{t}, t) \right) + \sigma_{t} \mathbf{z}$ 5: end for 6: return \mathbf{x}_{0}

L2-loss (MSE) between true and predicted Gaussian noise at time step t use position embeddings (as network parameters are shared across time)

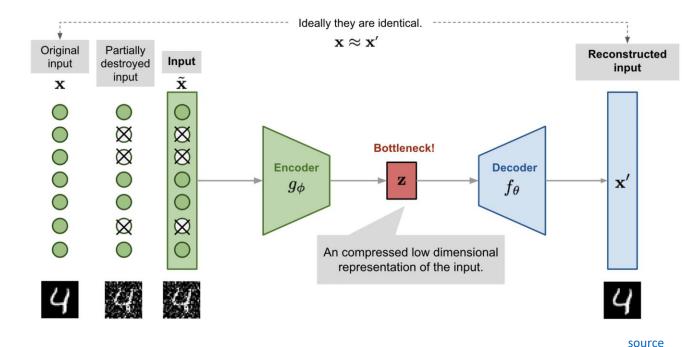

diffusion models can be interpreted as chain of denoising autoencoders (also connected to score-based generative modeling via Langevin dynamics)

Denoising Autoencoder

goal: avoid overfitting and improve robustness of plain autoencoder

learn to remove noise of distorted input $\tilde{x} \rightarrow$ restore original input x

similar to dropout

differences of diffusion models to typical denoising autoencoders:

- no bottleneck (care about output here, not internal representation): latent space with high dimensionality (same as original data)
- handle many different noise levels with single set of shared parameters

Latent Diffusion Model

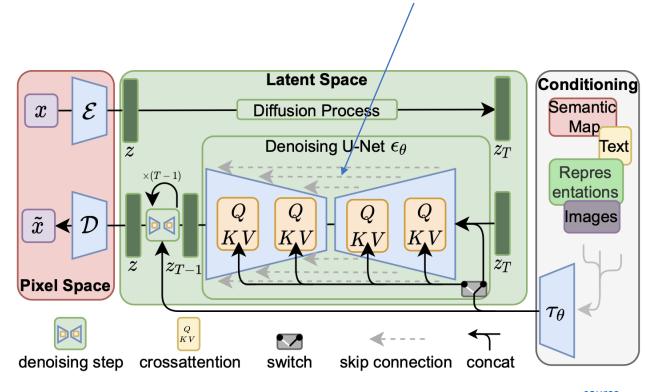

add noise to latent representation rather than raw data

→ significant speedup

diffusion models highly flexible in terms of architecture: only require same input and output dimensionality (autoencoder-like)

- often (convolutional) U-Net architectures
- but also (vision) transformers possible (e.g., <u>DiT</u>)

skip connections between layers operating at the same scale

source

use of attention mechanism for flexible conditioning

Conditioned Generation

Conditional GANs

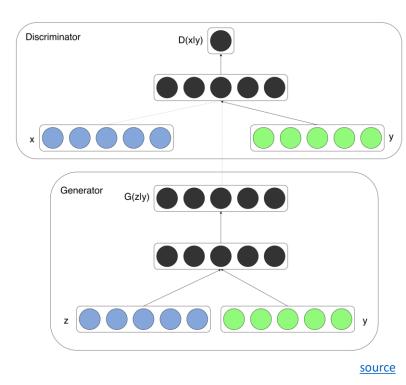

as discussed so far, generative methods give no control over what kind of data is generated (limited usability)

→ need for conditional approach (e.g., conditioning on describing text)

example GANs:

transform usual GAN to conditional model by feeding extra information y (e.g., class labels) as additional input layer into both generator and discriminator

$$L(\mathbf{x}_{i}) = E_{\mathbf{x} \sim p_{r}(\mathbf{x})} [\ln D(\mathbf{x}_{i}|y_{i})] + E_{\mathbf{x} \sim p_{g}(\mathbf{x})} [\ln (1 - D(\mathbf{x}_{i}|y_{i}))]$$

Guided Diffusion

ways to condition on class information in diffusion process:

- classifier guidance: perturbation of classconditional diffusion model by separately trained classifier model $p_{\theta}(y|x_t)$
 - $\widehat{\mu}_{\theta}(x_t|y) = \mu_{\theta}(x_t|y) + s \cdot \Sigma_{\theta}(x_t|y) \cdot \nabla_{x_t} \log p_{\theta}(y|x_t)$
 - guidance can also be free-form text, e.g., from CLIP model
- classifier-free guidance: randomly replace label in class-conditional diffusion model with null label during training

extrapolate in direction of conditioned model during sampling: $\hat{\epsilon}_{\theta}(x_t|y) \neq \hat{\epsilon}_{\theta}(x_t|\emptyset) + s \cdot (\hat{\epsilon}_{\theta}(x_t|y) - \hat{\epsilon}_{\theta}(x_t|\emptyset))$

similar idea as softmax temperature in auto-regressive LLMs

tradeoff between diversity (unconditioned) and fidelity (guidance)
